Sources of unfairness

Learning

Sources of unfairness

The data:

Is there bias in the data?

If the world is biased, the machine will be biased

Learning

Sources of unfairness

The data:

Is there bias in the data?

If the world is biased, the machine will be biased

Learning

The algorithm:

If we learn to answer correctly for the majority of people, it may be wrong for the minority

What is unfairness?

In computer science, we need numbers to tell us how unfair a machine is.

What is unfairness?

In computer science, we need numbers to tell us how unfair a machine is.

- **Positive predicted value (PPV):** the fraction of positive cases which were correctly predicted out of all the positive predictions. It is usually referred to as [precision](#), and represents the [probability](#) of a correct positive prediction. It is given by the following formula:

$$PPV = P(actual = + | prediction = +) = \frac{TP}{TP + FP}$$

- **False discovery rate (FDR):** the fraction of positive predictions which were actually negative out of all the positive predictions. It represents the [probability](#) of an erroneous positive prediction, and it is given by the following formula:

$$FDR = P(actual = - | prediction = +) = \frac{FP}{TP + FP}$$

- **Negative predicted value (NPV):** the fraction of negative cases which were correctly predicted out of all the negative predictions. It represents the [probability](#) of a correct negative prediction, and it is given by the following formula:

$$NPV = P(actual = - | prediction = -) = \frac{TN}{TN + FN}$$

- **False omission rate (FOR):** the fraction of negative predictions which were actually positive out of all the negative predictions. It represents the [probability](#) of an erroneous negative prediction, and it is given by the following formula:

$$FOR = P(actual = + | prediction = -) = \frac{FN}{TN + FN}$$

- **True positive rate (TPR):** the fraction of positive cases which were correctly predicted out of all the positive cases. It is usually referred to as sensitivity or recall, and it represents the [probability](#) of the positive subjects to be classified correctly as such. It is given by the formula:

$$TPR = P(prediction = + | actual = +) = \frac{TP}{TP + FN}$$

- **False negative rate (FNR):** the fraction of positive cases which were incorrectly predicted to be negative out of all the positive cases. It represents the [probability](#) of the positive subjects to be classified incorrectly as negative ones, and it is given by the formula:

$$FNR = P(prediction = - | actual = +) = \frac{FN}{TP + FN}$$

- **True negative rate (TNR):** the fraction of negative cases which were correctly predicted out of all the negative cases. It represents the [probability](#) of the negative subjects to be classified correctly as such, and it is given by the formula:

$$TNR = P(prediction = - | actual = -) = \frac{TN}{TN + FP}$$

- **False positive rate (FPR):** the fraction of negative cases which were incorrectly predicted to be positive out of all the negative cases. It represents the [probability](#) of the negative subjects to be classified incorrectly as positive ones, and it is given by the formula:

$$FPR = P(prediction = + | actual = -) = \frac{FP}{TN + FP}$$

Definitions based on predicted outcome [\[edit \]](#)

The definitions in this section focus on a predicted outcome R for various [distributions](#) of subjects. They are the simplest and most intuitive notions of fairness.

- **Demographic parity**, also referred to as **statistical parity**, **acceptance rate parity** and **benchmarking**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have equal probability of being assigned to the positive predicted class. This is, if the following formula is satisfied:

$$P(R = + | A = a) = P(R = + | A = b) \quad \forall a, b \in A$$

- **Conditional statistical parity**. Basically consists in the definition above, but restricted only to a [subset](#) of the instances. In mathematical notation this would be:

$$P(R = + | L = l, A = a) = P(R = + | L = l, A = b) \quad \forall a, b \in A \quad \forall l \in L$$

Definitions based on predicted probabilities and actual outcome [\[edit \]](#)

These definitions are based in the actual outcome Y and the predicted probability score S .

- **Test-fairness**, also known as **calibration** or **matching conditional frequencies**. A classifier satisfies this definition if individuals with the same predicted probability score S have the same probability of being classified in the positive class when they belong to either the protected or the unprotected group:

$$P(Y = + | S = s, A = a) = P(Y = + | S = s, A = b) \quad \forall s \in S \quad \forall a, b \in A$$

- **Well-calibration** is an extension of the previous definition. It states that when individuals inside or outside the protected group have the same predicted probability score S they must have the same probability of being classified in the positive class, and this probability must be equal to S :

$$P(Y = + | S = s, A = a) = P(Y = + | S = s, A = b) = s \quad \forall s \in S \quad \forall a, b \in A$$

- **Balance for positive class**. A classifier satisfies this definition if the subjects constituting the positive class from both protected and unprotected groups have equal average predicted probability score S . This means that the expected value of probability score for the protected and unprotected groups with positive actual outcome Y is the same, satisfying the formula:

$$E(S | Y = +, A = a) = E(S | Y = +, A = b) \quad \forall a, b \in A$$

- **Balance for negative class**. A classifier satisfies this definition if the subjects constituting the negative class from both protected and unprotected groups have equal average predicted probability score S . This means that the expected value of probability score for the protected and unprotected groups with negative actual outcome Y is the same, satisfying the formula:

$$E(S | Y = -, A = a) = E(S | Y = -, A = b) \quad \forall a, b \in A$$

Definitions based on predicted and actual outcomes [\[edit \]](#)

These definitions not only considers the predicted outcome R but also compare it to the actual outcome Y :

- **Predictive parity**, also referred to as **outcome test**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have equal PPV. This is, if the following formula is satisfied:

$$P(Y = + | R = +, A = a) = P(Y = + | R = +, A = b) \quad \forall a, b \in A$$

Mathematically, if a classifier has equal PPV for both groups, it will also have equal FDR, satisfying the formula:

$$P(Y = - | R = +, A = a) = P(Y = - | R = +, A = b) \quad \forall a, b \in A$$

- **False positive error rate balance**, also referred to as **predictive equality**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have equal FPR. This is, if the following formula is satisfied:

$$P(R = + | Y = -, A = a) = P(R = + | Y = -, A = b) \quad \forall a, b \in A$$

Mathematically, if a classifier has equal FPR for both groups, it will also have equal TNR, satisfying the formula:

$$P(R = - | Y = -, A = a) = P(R = - | Y = -, A = b) \quad \forall a, b \in A$$

- **False negative error rate balance**, also referred to as **equal opportunity**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have equal FNR. This is, if the following formula is satisfied:

$$P(R = - | Y = +, A = a) = P(R = - | Y = +, A = b) \quad \forall a, b \in A$$

Mathematically, if a classifier has equal FNR for both groups, it will also have equal TPR, satisfying the formula:

$$P(R = + | Y = +, A = a) = P(R = + | Y = +, A = b) \quad \forall a, b \in A$$

- **Equalized odds**, also referred to as **conditional procedure accuracy equality** and **disparate mistreatment**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have equal TPR and equal FPR, satisfying the formula:

$$P(R = + | Y = y, A = a) = P(R = + | Y = y, A = b) \quad y \in \{+, -\} \quad \forall a, b \in A$$

- **Conditional use accuracy equality**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have equal PPV and equal NPV, satisfying the formula:

$$P(Y = y | R = y, A = a) = P(Y = y | R = y, A = b) \quad y \in \{+, -\} \quad \forall a, b \in A$$

- **Overall accuracy equality**. A classifier satisfies this definition if the subject in the protected and unprotected groups have equal prediction accuracy, that is, the probability of a subject from one class to be assigned to it. This is, if it satisfies the following formula:

$$P(R = Y | A = a) = P(R = Y | A = b) \quad \forall a, b \in A$$

- **Treatment equality**. A classifier satisfies this definition if the subjects in the protected and unprotected groups have an equal ratio of FN and FP, satisfying the formula:

$$\frac{FN_{A=a}}{FP_{A=a}} = \frac{FN_{A=b}}{FP_{A=b}}$$

What is unfairness?

In computer science, we need numbers to tell us how unfair a machine is.

- **Positive predicted value (PPV):** the fraction of positive cases which were correctly predicted out of all the positive predictions. It is usually referred to as precision, and represents the probability of a correct positive prediction. It is given by the following formula:

$$PPV = P(actual = + | prediction = +) = \frac{TP}{TP + FP}$$

- **False discovery rate (FDR):** the fraction of positive predictions which were actually negative out of all the positive predictions. It represents the probability of an erroneous positive prediction, and it is given by the following formula:

$$FDR = P(actual = - | prediction = +) = \frac{FP}{TP + FP}$$

- **Negative predicted value (NPV):** the fraction of negative cases which were correctly predicted out of all the negative predictions. It represents the probability of a correct negative prediction, and it is given by the following formula:

$$NPV = P(actual = - | prediction = -) = \frac{TN}{TN + FN}$$

- **False omission rate (FOR):** the fraction of negative predictions which were actually positive out of all the negative predictions. It represents the probability of an erroneous negative prediction, and it is given by the following formula:

$$FOR = P(actual = + | prediction = -) = \frac{FN}{TN + FN}$$

- **True positive rate (TPR):** the fraction of positive cases which were correctly predicted to be positive out of all the positive cases. It is usually referred to as sensitivity or recall, and it represents the probability of a correct positive prediction. It is given by the formula:

$$TPR = P(prediction = + | actual = +) = \frac{TP}{TP + FN}$$

- **False negative rate (FNR):** the fraction of positive cases which were incorrectly predicted to be negative out of all the positive cases. It represents the probability of the positive subjects to be classified incorrectly as negative ones, and it is given by the formula:

$$FNR = P(prediction = - | actual = +) = \frac{FN}{TP + FN}$$

- **True negative rate (TNR):** the fraction of negative cases which were correctly predicted out of all the negative cases. It represents the probability of the negative subjects to be classified correctly as such, and it is given by the formula:

$$TNR = P(prediction = - | actual = -) = \frac{TN}{TN + FP}$$

- **False positive rate (FPR):** the fraction of negative cases which were incorrectly predicted to be positive out of all the negative cases. It represents the probability of the negative subjects to be classified incorrectly as positive ones, and it is given by the formula:

$$FPR = P(prediction = + | actual = -) = \frac{FP}{TN + FP}$$
